### **Short review**

Let us recall: we have a population characteristic X, whose pdf  $f(x; \theta)$  depends on  $\theta$ , the target parameter to be estimated. The estimation is done based on a sample of size n, i.e. sample variables  $X_1, X_2, \ldots, X_n$  that are iid, with the same pdf as X.

We set up two hypotheses, the *null* hypothesis, always simple, i.e.

$$H_0: \theta = \theta_0$$

and one of the alternative hypotheses

$$H_1: \ \theta < \theta_0 \ (\text{left-tailed test}),$$
  $H_1: \ \theta > \theta_0 \ (\text{right-tailed test}),$   $H_1: \ \theta \neq \theta_0 \ (\text{two-tailed test}).$  (4.1)

We want to decide if  $H_0$  is rejected (in favor of  $H_1$ ) or not rejected (accepted). We use a test statistic TS (with the same properties as the pivot in CI's) and a rejection (critical) region RR, such that for a given significance level  $\alpha \in (0,1)$ ,

$$P(\text{type I error}) = P(\text{ reject } H_0 \mid H_0) = P(TS \in RR \mid H_0) = \alpha.$$
 (4.2)

The probability of a type II error is

$$P(\text{ type II error}) = P(\text{ not reject } H_0 \mid H_1) = P(TS \notin RR \mid H_1) = \beta.$$

In general, the significance level  $\alpha$  is preset and a procedure is given for finding an appropriate rejection region, such that  $\beta$  is also reasonably small.

We considered the case where for a target parameter  $\theta$ ,  $\overline{\theta}$  is an unbiased estimator  $(E(\overline{\theta}) = \theta)$ , with standard error  $\sigma_{\overline{\theta}}$ , such that, under certain conditions, it is known that

$$Z = \frac{\overline{\theta} - \theta}{\sigma_{\overline{\theta}}} \left( = \frac{\overline{\theta} - E(\overline{\theta})}{\sigma(\overline{\theta})} \right) \tag{4.3}$$

has an approximately Standard Normal N(0,1) distribution. Using Z as a test statistic, we found

the rejection regions for the three alternatives (4.1) as

$$RR: \begin{cases} \{Z_0 \le z_{\alpha}\} \\ \{Z_0 \ge z_{1-\alpha}\} \\ \{Z_0 \le z_{\frac{\alpha}{2}} \text{ or } Z_0 \ge z_{1-\frac{\alpha}{2}}\} = \{|Z_0| \ge z_{1-\frac{\alpha}{2}}\}. \end{cases}$$

$$(4.4)$$

Alternatively, we perform a *significance test*. We compute the P-value of the test, the probability of observing a value at least as extreme (in the sense of the test conducted) of the test statistic TS as the value observed from the sample,  $TS_0$ , under the assumption that  $H_0$  is true. In general, for the three alternatives (4.1), if  $TS_0$  is the value of the test statistic TS under the assumption that  $H_0$  is true and F is the cdf of TS, the P-value is computed by

$$P = \begin{cases} P(TS < TS_0 \mid H_0) &= F(TS_0) \\ P(TS > TS_0 \mid H_0) &= 1 - F(TS_0) \\ 2 \cdot \min\{P(TS < TS_0 \mid H_0), P(TS > TS_0 \mid H_0)\} &= 2 \cdot \min\{F(TS_0), 1 - F(TS_0)\}. \end{cases}$$
(4.5)

Then the decision will be

if 
$$P \le \alpha$$
, reject  $H_0$ ,  
if  $P > \alpha$ , do not reject  $H_0$ . (4.6)

So, more precisely, the P-value of a test is the smallest level at which we could have preset  $\alpha$  and still have been able to reject  $H_0$ , or the lowest significance level that *forces* rejection of  $H_0$ , i.e. the *minimum rejection level*.

# 4.4 Tests for the Parameters of One Population

Let X be a population characteristic, with pdf  $f(x;\theta)$ , mean  $E(X)=\mu$  and variance  $V(X)=\sigma^2$ . Let  $X_1,X_2,\ldots,X_n$  be sample variables.

## Tests for the mean of a population, $\theta = \mu$

We test the hypotheses

$$H_0: \quad \mu = \mu_0$$
, versus one of 
$$H_1: \begin{cases} \mu < \mu_0 \\ \mu > \mu_0 \\ \mu \neq \mu_0, \end{cases} \tag{4.7}$$

under the assumption that either X is approximately Normally  $N(\mu, \sigma)$  distributed or that the sample is large (n > 30).

## Case $\sigma$ known (ztest)

We use the test statistic

$$TS = Z = \frac{\overline{X} - \mu}{\frac{\sigma}{\sqrt{n}}} \in N(0, 1), \tag{4.8}$$

with observed value

$$Z_0 = \frac{\overline{X} - \mu_0}{\frac{\sigma}{\sqrt{n}}}. (4.9)$$

Then, as before, at the  $\alpha \in (0,1)$  significance level, the rejection region for each test will be given by

$$RR: \begin{cases} \{Z_0 \le z_{\alpha}\} \\ \{Z_0 \ge z_{1-\alpha}\} \\ \{|Z_0| \ge z_{1-\frac{\alpha}{2}}\} \end{cases}$$
 (4.10)

and the P-value will be computed as

$$P = \begin{cases} P(Z \le Z_0 \mid H_0) &= \Phi(Z_0) \\ P(Z \ge Z_0 \mid H_0) &= 1 - \Phi(Z_0) \\ P(|Z| \ge |Z_0| \mid H_0) &= 2 (1 - \Phi(|Z_0|)), \end{cases}$$
(4.11)

since N(0,1) is symmetric, where

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-\frac{t^2}{2}} dt$$

is Laplace's function, the cdf for the Standard Normal N(0,1) distribution.

# Case $\sigma$ unknown (ttest)

In this case, we use the test statistic

$$TS = T = \frac{\overline{X} - \mu}{\frac{s}{\sqrt{n}}} \in T(n-1),$$
 (4.12)

with observed value

$$T_0 = \frac{\overline{X} - \mu_0}{\frac{s}{\sqrt{n}}}. (4.13)$$

Similarly to the previous case, we find the rejection region for the three alternatives as

$$RR: \begin{cases} \{T_0 \le t_{\alpha}\} \\ \{T_0 \ge t_{1-\alpha}\} \\ \{|T_0| \ge t_{1-\frac{\alpha}{2}}\}, \end{cases}$$
(4.14)

and compute the P-value by

$$P = \begin{cases} P(T \le T_0 \mid H_0) &= F(T_0) \\ P(T \ge T_0 \mid H_0) &= 1 - F(T_0) \\ P(|T| \ge |T_0| \mid H_0) &= 2(1 - F(|T_0|)), \end{cases}$$
(4.15)

where the cdf F and the quantiles refer to the T(n-1) distribution.

## Tests for the variance of a population, $\theta = \sigma^2$ (vartest)

Assuming that X has a Normal  $N(\mu, \sigma)$  distribution, we test the hypotheses

$$H_{0}: \quad \sigma^{2} = \sigma_{0}^{2}, \qquad H_{0}: \quad \sigma = \sigma_{0},$$

$$H_{1}: \begin{cases} \sigma^{2} < \sigma_{0}^{2} \\ \sigma^{2} > \sigma_{0}^{2} \end{cases} \quad \text{equivalent to} \quad H_{1}: \begin{cases} \sigma < \sigma_{0} \\ \sigma > \sigma_{0} \\ \sigma \neq \sigma_{0}. \end{cases}$$

$$(4.16)$$

The test statistic will be

$$TS = V = \frac{(n-1)s^2}{\sigma^2} \in \chi^2(n-1),$$
 (4.17)

with observed value

$$V_0 = \frac{(n-1)s^2}{\sigma_0^2}. (4.18)$$

Even though the  $\chi^2(n-1)$  distribution is not symmetric, we use the same line of reasoning and computations to find the rejection region for the three alternatives:

$$RR: \begin{cases} \{V_0 \le \chi_{\alpha}^2\} \\ \{V_0 \ge \chi_{1-\alpha}^2\} \\ \{V_0 \le \chi_{\frac{\alpha}{2}}^2 \text{ or } V_0 \ge \chi_{1-\frac{\alpha}{2}}^2\}. \end{cases}$$

$$(4.19)$$

Same goes for the computation of the *P*-values:

$$P = \begin{cases} P(V \le V_0 \mid H_0) &= F(V_0) \\ P(V \ge V_0 \mid H_0) &= 1 - F(V_0) \\ 2 \cdot \min\{P(V \le V_0 \mid H_0), P(V \ge V_0 \mid H_0)\} &= 2 \cdot \min\{F(V_0), 1 - F(V_0)\}, \end{cases}$$

$$(4.20)$$

where the cdf F and the quantiles refer to the  $\chi^2(n-1)$  distribution.

**Example 4.1.** Let us consider again the problem in Example 4.4 (Lecture 10): The number of monthly sales at a firm is known to have a mean of 20 and a standard deviation of 4 and all salary, tax and bonus figures are based on these values. Suppose that for the sample considered (of 36 randomly selected salespeople), the standard deviation is found to be s=4.5. Assuming that the number of monthly sales at that firm is Normally distributed, at the 5% significance level, does the assumption on  $\sigma$  seem to be correct?

**Solution.** We are now testing the variance. We want to know if the value  $\sigma = 4$  is correct *or not*, so, this will be a *two-tailed* test.

$$H_0: \quad \sigma = 4$$
  
 $H_1: \quad \sigma \neq 4$ ,

i.e.,

$$H_0: \ \sigma^2 = 16 = \sigma_0^2$$
  
 $H_1: \ \sigma^2 \neq 16 = \sigma_0^2$ 

We have n=36 and  $s^2=(4.5)^2=20.25$ . The observed value of the test statistic is

$$V_0 = \frac{(n-1)s^2}{\sigma_0^2} = \frac{35 \cdot 20.25}{16} = 44.2969.$$

The significance level is  $\alpha = 0.05$  and the two quantiles for the  $\chi^2(35)$  distribution are

$$\chi^2_{0.025} = 20.5694,$$
  
 $\chi^2_{0.075} = 53.2033.$ 

Then the rejection region is

$$RR = (-\infty, 20.5694] \cup [53.2033, \infty),$$

which does not include the value  $V_0$ . Therefore, the decision is to not reject the null hypothesis, i.e. to conclude that the assumption  $\sigma = 4$  is correct.

On the other hand, the P-value is

$$P = 2 \cdot \min\{P(V \le V_0), P(V \ge V_0)\} = 2 \cdot \min\{0.8652, 0.1348\} = 0.2697.$$

Since

$$\alpha = 0.05 < 0.2697 = P$$

the decision is to *not reject* the null hypothesis.

Notice that the significance test tells us more! Since the P-value is so large (remember, it is comparable to a probability of an error, so a small quantity), not only at the 5% significance level we decide to accept  $H_0$ , but at any reasonable significance level the decision would be the same. That means that the data strongly suggests that  $H_0$  is true and should not be rejected. Even though the sample standard deviation is not equal to 4, still, statistically, the data strongly suggests that the population standard deviation is 4. We should be careful not to extrapolate the property of one sample to the entire population (data from a sample may be misleading, if it is not used properly ...)

# 4.5 Tests for Comparing the Parameters of Two Populations

Assume we have two population characteristics  $X_{(1)}$  and  $X_{(2)}$ , with means and variances  $E(X_{(1)}) = \mu_1, V(X_{(1)}) = \sigma_1^2$  and  $E(X_{(2)}) = \mu_2, V(X_{(2)}) = \sigma_2^2$ , respectively. We draw two independent random samples

$$X_{11}, \ldots, X_{1n}$$
 and  $X_{21}, \ldots, X_{2n}$ 

with sample means

$$\overline{X}_1 = \frac{1}{n_1} \sum_{i=1}^{n_1} X_{1i}, \quad \overline{X}_2 = \frac{1}{n_2} \sum_{j=1}^{n_2} X_{2j}$$

and sample variances

$$s_1^2 = \frac{1}{n_1 - 1} \sum_{i=1}^{n_1} (X_{1i} - \overline{X}_1)^2, \quad s_2^2 = \frac{1}{n_2 - 1} \sum_{j=1}^{n_2} (X_{2j} - \overline{X}_2)^2,$$

respectively. In addition, we have

$$s_p^2 = \frac{\sum_{i=1}^{n_1} (X_{1i} - \overline{X}_1)^2 + \sum_{j=1}^{n_2} (X_{2j} - \overline{X}_2)^2}{n_1 + n_2 - 2} = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}$$

the *pooled variance* of the two samples, a variance that considers the sample data from both samples.

Recall that when comparing the means of two populations, we estimate their *difference* and when comparing the variances, we estimate their *ratio*.

The formulas for testing hypotheses for the difference of means  $\mu_1 - \mu_2$  and for the ratio of variances  $\frac{\sigma_1^2}{\sigma_2^2}$  are based on the same results (which follow either from properties of random variables, or are the consequence of some CLT) that were used for finding confidence intervals (see Propositions 3.1 and 3.2 in Lecture 10).

### Tests for the difference of means, $\theta = \mu_1 - \mu_2$

We test the hypotheses

$$H_{0}: \quad \mu_{1} - \mu_{2} = 0, \qquad H_{0}: \quad \mu_{1} = \mu_{2},$$

$$H_{1}: \begin{cases} \mu_{1} - \mu_{2} < 0 \\ \mu_{1} - \mu_{2} > 0 \\ \mu_{1} - \mu_{2} \neq 0, \end{cases}$$
 equivalent to 
$$H_{1}: \begin{cases} \mu_{1} < \mu_{2} \\ \mu_{1} > \mu_{2} \\ \mu_{1} \neq \mu_{2}, \end{cases}$$
 (4.21)

under the assumption that either  $X_{(1)}$  and  $X_{(2)}$  have approximately Normal distributions or that the samples are large enough  $(n_1 + n_2 > 40)$ .

### Case $\sigma_1, \sigma_2$ known

We use the test statistic

$$TS = Z = \frac{(\overline{X}_1 - \overline{X}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \in N(0, 1), \tag{4.22}$$

with observed value

$$Z_0 = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}}.$$
 (4.23)

The rejection regions and P-values for the three alternatives are then given by equations (4.10)-(4.11), with  $Z_0$  from (4.23).

## Case $\sigma_1 = \sigma_2$ unknown (ttest2)

The test statistic is

$$TS = T = \frac{(\overline{X}_1 - \overline{X}_2) - (\mu_1 - \mu_2)}{s_p \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \in T(n_1 + n_2 - 2), \tag{4.24}$$

with observed value

$$T_0 = \frac{\overline{X}_1 - \overline{X}_2}{s_p \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}. (4.25)$$

The rejection regions and P-values for the three alternatives are then given by equations (4.14)-(4.15), where  $T_0$  is given in (4.25) and the cdf F and the quantiles refer to the  $T(n_1 + n_2 - 2)$  distribution.

# Case $\sigma_1, \sigma_2$ unknown (ttest2)

We now use the test statistic

$$TS = T^* = \frac{(\overline{X}_1 - \overline{X}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \in T(n), \tag{4.26}$$

where 
$$\frac{1}{n} = \frac{c^2}{n_1 - 1} + \frac{(1 - c)^2}{n_2 - 1}$$
 and  $c = \frac{\frac{s_1^2}{n_1}}{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}$ .

The observed value of the test statistic is

$$T_0^* = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}. (4.27)$$

The rejection regions and P-values for the three alternatives are again as in equations (4.14)-(4.15), with  $T_0$  replaced by  $T_0^*$  from (4.27). The cdf F and the quantiles refer to the T(n) distribution.

**Remark 4.2.** The same Matlab command **ttest2** performs a *T*-test for the difference of two population means, when the variances are *not* assumed equal, with the option *vartype* set on "unequal"

(the default being "equal", when it can be omitted).

Tests for the ratio of variances,  $\theta = \frac{\sigma_1^2}{\sigma_2^2}$  (vartest2)

Assuming that both  $X_{(1)}$  and  $X_{(1)}$  have Normal distributions, we test the hypotheses

$$H_{0}: \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} = 1,$$

$$H_{0}: \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} < 1$$

$$H_{1}: \begin{cases} \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} < 1 \\ \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} < 1 \\ \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} > 1 \end{cases} <=> H_{1}: \begin{cases} \sigma_{1}^{2} < \sigma_{2}^{2} \\ \sigma_{1}^{2} > \sigma_{2}^{2} \\ \frac{\sigma_{1}^{2}}{\sigma_{2}^{2}} \neq 1, \end{cases} <=> H_{1}: \begin{cases} \sigma_{1} < \sigma_{2} \\ \sigma_{1}^{2} > \sigma_{2}^{2} \\ \sigma_{1}^{2} \neq \sigma_{2}^{2}, \end{cases} <=> H_{1}: \begin{cases} \sigma_{1} < \sigma_{2} \\ \sigma_{1} > \sigma_{2} \\ \sigma_{1} \neq \sigma_{2}. \end{cases}$$

$$(4.28)$$

The test statistic used is

$$TS = F = \frac{s_1^2/\sigma_1^2}{s_2^2/\sigma_2^2} \in F(n_1 - 1, n_2 - 1),$$
 (4.29)

with observed value

$$F_0 = \frac{s_1^2}{s_2^2}. (4.30)$$

Again, just like in the case of one population variance, the  $F(n_1 - 1, n_2 - 1)$  distribution is not symmetric, but proceeding as before, we find the rejection region for the three alternatives as

$$RR: \begin{cases} \{F_0 \le f_{\alpha}\} \\ \{F_0 \ge f_{1-\alpha}\} \\ \{F_0 \le f_{\frac{\alpha}{2}} \text{ or } F_0 \ge f_{1-\frac{\alpha}{2}}\}. \end{cases}$$
 (4.31)

and the P-values given by

$$P = \begin{cases} P(F \le F_0 \mid H_0) &= F(F_0) \\ P(F \ge F_0 \mid H_0) &= 1 - F(F_0) \\ 2 \cdot \min\{P(F \le F_0 \mid H_0), P(F \ge F_0 \mid H_0)\} &= 2 \cdot \min\{F(F_0), 1 - F(F_0)\}, \end{cases}$$

$$(4.32)$$

where the cdf F and the quantiles refer to the  $F(n_1 - 1, n_2 - 1)$  distribution.

**Example 4.3.** Suppose the strengths to a certain load of two types of material, M1 and M2, are

studied, knowing that they are approximately Normally distributed. The more weight they can resist to, the stronger they are. Two independent random samples are drawn and they yield the following data.

$$\begin{array}{c|ccccc} M1 & M2 \\ \hline n_1 & = & 25 & n_2 & = & 16 \\ \overline{X}_1 & = & 380 & \overline{X}_2 & = & 370 \\ s_1^2 & = & 537 & s_2^2 & = & 196 \\ \hline \end{array}$$

- a) At the 5% significance level, do the variances of the two populations seem to be equal or not?
- b) At the same significance level, does the data suggest that on average, M1 is stronger than M2? (In both parts, perform both hypothesis and significance testing).

#### Solution.

a) First, we compare the variances of the two populations, so we know which way to proceed for comparing the means. We want to know if they are equal or not, so it is a two-tailed test. Hence, our hypotheses are

$$H_0: \ \sigma_1^2 = \sigma_2^2$$
  
 $H_1: \ \sigma_1^2 \neq \sigma_2^2$ .

The observed value of the test statistic is

$$F_0 = \frac{s_1^2}{s_2^2} = \frac{537}{196} = 2.7398.$$

For  $\alpha = 0.05$ ,  $n_1 = 25$  and  $n_2 = 16$ , the quantiles for the F(24, 15) distribution are

$$f_{\frac{\alpha}{2}} = f_{0.025} = 0.4103$$
  
 $f_{1-\frac{\alpha}{2}} = f_{0.975} = 2.7006.$ 

Thus, the rejection region for our test is

$$RR = (-\infty, 0.4103] \cup [2.7006, \infty)$$

and clearly,  $F_0 \in RR$ . Thus we reject  $H_0$  in favor of  $H_1$ , i.e. we conclude that the data suggests that the population variances are *different*.

Let us also perform a significance test. The P-value of this (two-tailed) test is

$$P = 2 \cdot \min\{P(F \le F_0), P(F \ge F_0)\} = 2 \cdot \min\{0.9765, 0.0235\} = 0.0469.$$

Since our  $\alpha > P$ , the "minimum rejection significance level", we reject  $H_0$ .

**Note.** We now know that for instance, at 1% significance level (or any level less than 4.69%), we would have *not* rejected the null hypothesis. This goes to show that the data can be "misleading". Simply comparing the values of the sample functions does not necessarily mean that the same thing will be true for the corresponding population parameters. Here,  $s_1^2$  is *much* larger than  $s_2^2$ , yet at 1% significance level, we would have concluded that the population variances seem to be equal.

b) Next we want to compare the population means. If M1 is to be *stronger* than M2 on average, than we must perform a *right*-tailed test:

$$H_0: \mu_1 = \mu_2$$
  
 $H_1: \mu_1 > \mu_2$ 

Which one of the tests for the difference of means should we use? The answer is in part a). At this significance level, the variances are unknown and *different*.

Then the value of the test statistic is, by (4.27)

$$T_0^* = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} = \frac{380 - 370}{\sqrt{\frac{537}{25} + \frac{196}{16}}} = 1.7218.$$

To find the rejection region, we compute

$$c = 0.6368, \quad n = 38.9244 \approx 39$$

and the quantile for the T(39) distribution

$$t_{1-\alpha} = t_{0.95} = 1.6849.$$

Then the rejection region of the test is

$$RR = [1.6849, \infty),$$

which includes the value  $T_0^*$ , so we reject  $H_0$  in favor of  $H_1$ . So we conclude that yes, the data suggests that material M1 is, on average, stronger than material M2.

On the other hand, the *P*-value of this test is

$$P = P(T^* \ge T_0^*) = 1 - F(T_0^*) = 1 - F(1.7218) = 0.0465,$$

where F is the cdf of the T(39) distribution. Again, the P-value is lower than  $\alpha = 0.05$ , which forces the rejection of  $H_0$ .

### Remark 4.4.

1. As mentioned before, both hypothesis and significance testing lead to the same conclusion. From the implementation point of view, significance testing is more efficient, since it avoids the inversion of a cdf (i.e. computation of quantiles), which is often a complicated improper integral. This is the reason why, although the main tests *are* implemented in Matlab, the rejection regions *are not* computed.

2. Many tests (and formulas for CI's) work under the assumption of Normality of the population from which the sample was drawn. In practice, when there are outliers in the data, that is rarely the case. How important is this assumption of Normality and how affected are the results of these tests by small departures from model assumptions? Z-tests and T-tests work well even when the underlying population is not quite Normally distributed. From this point of view, they are called **robust** tests.  $\chi^2$ -tests and F-tests, however, are *not* robust, they perform very poorly when the assumption of Normality is breached. In modern Statistics there is an ongoing search for finding robust methods of estimation for variances.
